Abstract

Reconstructions of former ice masses from glacial geomorphology help constrain the nature and timing of glaciation in relation to climatic forcing. This paper presents a new reconstruction of the glacial history of five ice lobes in southernmost South America: the Bahía Inútil – San Sebastián, Magellan, Otway, Skyring, and Río Gallegos ice lobes. We use previous geomorphological mapping of glacial landforms to reconstruct former glacial limits and proglacial lakes, demarcate flow-sets from the distribution of glacial lineations, and evaluate glacial landsystem signatures and their palaeoglaciological implications. Evidence suggests that the ice lobes predominantly reflect active temperate glacial landsystems, which may have switched to polythermal systems when periods of cold-based ice developed ephemerally. This complex landsystem signature implies that the ice lobes were sensitive to regional climate variability, with active re-advances during overall retreat of the ice margins. There is also evidence for periods of fast ice flow and possible surge-like activity in the region, followed by the rapid retreat or even collapse of some of the ice lobes in association with proglacial lakes. Constraining our new reconstruction with published chronological information suggests that at least some of the ice lobes advanced prior to the global Last Glacial Maximum (gLGM: ca. 26.5-19 ka) during the last glacial cycle. Our new reconstruction demonstrates a more complex picture of ice dynamics than has previously been portrayed, and one in which the advance and retreat of the ice lobes was likely to have been primarily driven by changes in climate. As such, ice advances prior to the gLGM in the southernmost part of the Patagonian Ice Sheet are likely to be indicative of a wider climatic forcing at this time.

33 **1 Introduction**

34 Well-preserved glacial geomorphology relating to the former Patagonian Ice Sheet provides
35 a record of the fluctuations of its margins throughout the Quaternary (Clapperton, 1993;
36 Glasser & Jansson, 2008; Glasser et al., 2008). This record can also be used to reconstruct
37 ice-sheet dynamics (Glasser & Jansson, 2005; Glasser et al., 2005; Lovell et al., 2012) and
38 may be supplemented with chronological information to constrain how the ice sheet changed
39 over time as a result of climatic forcing (e.g. McCulloch et al., 2005b; Douglass et al., 2006;
40 Kaplan et al., 2008a, 2008b; Hein et al., 2010). For example, the southernmost part of the
41 ice sheet was heavily influenced by changes in temperature and precipitation linked to the
42 atmospheric Southern Westerly Winds and oceanic frontal positions (Lamy et al., 2007;
43 Kaplan et al., 2008a; Kilian & Lamy, 2012). Climate reconstructions prior to the Holocene are
44 uncertain, but temperatures at the global Last Glacial Maximum (gLGM: ca. 26.5-19 ka,
45 Clark et al., 2009) may have been as much as 7-8°C lower than present (Benn &
46 Clapperton, 2000a; Caniupán et al., 2011). Consequently, reconstruction of the
47 southernmost ice lobes can help to establish likely changes in these climatic systems over
48 time, but this process requires a robust understanding of the glacial history and ice dynamics
49 (Sugden et al., 2005; Kilian & Lamy, 2012).

50 Previous studies of the southernmost ice lobes of the Patagonian Ice Sheet have tended to
51 focus on dating glacial limits, with a particular emphasis on constraining the local Last
52 Glacial Maximum in relation to the gLGM and younger glacial limits. However, there has
53 been a lack of consistent, detailed mapping across the region (Darvill et al., 2014), and there
54 remains uncertainty about the timing and nature of pre-gLGM glacial advances (Kaplan et
55 al., 2007). Indeed, it has been shown that glacial limits of the Bahía Inútil – San Sebastián
56 (BI-SSb) ice lobe that were previously thought to be pre-last glacial cycle were actually
57 deposited more recently (Darvill et al., 2015b). This suggests that significant glacier
58 advances during Marine Isotope Stage (MIS) 3 (and possibly MIS 4) are represented in the
59 area, perhaps linked to wider glacial activity in the southern mid-latitudes at this time

(Putnam et al., 2013; Kelley et al., 2014; Darvill et al., 2015b; Doughty et al., 2015; Schaefer et al., 2015; Eaves et al., 2016). In this paper, we use a previously published map of the region, largely based on relatively high-resolution satellite imagery (~30 m resolution; Darvill et al., 2014), and apply glacial inversion methods to produce a new palaeoglaciological reconstruction of the dynamics of the ice sheet that is further constrained through analysis of published chronological data.

2 Study area

The study area lies between 51-55°S and 68-73°W, and encompasses the area occupied by five former piedmont ice lobes of the Patagonian Ice Sheet (Figure 1). From south to north, these are the Bahía Inútil – San Sebastián (BI-SSb), Magellan, Otway, Skyring and Río Gallegos lobes. The topography of the area changes dramatically from southwest to northeast, with the southern Andes (dominated by the Cordillera Darwin) marking the southern and western boundaries and casting a strong rain shadow over the low, flat pampas and coastal areas to the north and east (Coronato et al., 2008). The locations of the former ice lobes are marked by prominent straits and sounds, which were established by one or more major glacial events during the Quaternary (Rabassa, 2008; Kaplan et al., 2009). Glacial geomorphology relating to the former ice lobes was first described in detail by Caldenius (1932) and has since been updated, and sometimes reinterpreted, by numerous workers (Clapperton et al., 1995; Rabassa et al., 2000; Benn & Clapperton, 2000b, 2000a; Meglioli, 1992; Bentley et al., 2005; McCulloch et al., 2005b; Lovell et al., 2011, 2012; Darvill et al., 2014, 2015a).

Meglioli (1992) used weathering indices to establish an age model for the region, whereby nested moraine limits were deposited during successive glacial episodes from MIS 12 to 2 (Coronato et al., 2004). Subsequently, a range of dating techniques have been used to constrain the ages of some moraine limits deposited during or after the gLGM (Rutter et al.,

86 1989; Porter, 1990; Meglioli, 1992; Clapperton et al., 1995; McCulloch et al., 2005b; Sagredo
87 et al., 2011; Blomdin et al., 2012; Hall et al., 2013). Age constraints prior to the gLGM are
88 limited (Kaplan et al., 2007; Evenson et al., 2009; Darvill et al., 2015a, 2015b), although
89 $^{40}\text{Ar}/^{39}\text{Ar}$ dates suggest that the outermost limits of the Río Gallegos, Skyring, Otway and
90 Magellan lobes date to 1070-450 ka (Meglioli, 1992; Singer et al., 2004). By contrast, Darvill
91 et al. (2015b) recently demonstrated that one of two outer limits of the BI-SSb lobe was
92 deposited much more recently, at ca. 30 ka. Beyond this, the Magellan and Río Gallegos
93 lobes have only a few scattered cosmogenic nuclide exposure ages (Kaplan et al., 2007;
94 Evenson et al., 2009; Sagredo et al., 2011) and the Skyring and Otway lobes have no age
95 controls prior to around 15 ka (Kilian et al., 2007, 2013).

96 Relatively little attention has been given to the nature of ice dynamics recorded by the glacial
97 geomorphology, with the exception of localised studies on the gLGM or post-gLGM limits.
98 Previous work has highlighted factors affecting ice-lobe dynamics and rates of advance and
99 retreat, such as the influence of pro-glacial lakes (Porter et al., 1992; Lovell et al., 2012),
100 subglacial thermal regime (Benn & Clapperton, 2000b, 2000a; Bentley et al., 2005) and
101 evidence for rapid ice flow over a soft-sediment bed (Clapperton et al., 1995; Lovell et al.,
102 2012). As such, there is a need for a regional glacial history that incorporates
103 geomorphological evidence for ice dynamics and reassesses previously published
104 chronological data.

105

106 **3 Methods**

107 **3.1 Geomorphological mapping**

108 This paper uses a previously-published glacial geomorphological map of the region (Darvill
109 et al., 2014) to build a new palaeoglaciological reconstruction. Glacial landforms were
110 mapped from Landsat and ASTER satellite images, aerial photographs, Google Earth
111 imagery, and SRTM digital elevation data, and much of the area was also cross-checked in

the field, with an emphasis on verifying mapped landforms and identifying cross-cutting relationships of features (Darvill et al., 2014).

114

115 **3.2 Glacial flow-sets, ice margins and landsystems**

Glacial landforms can yield information on the extent of former ice advances and ice sheet dynamics using glacial inversion methods (Kleman et al., 2006). Glacial lineation flow-sets reveal coherent patterns of former ice flow trajectories and a landsystem approach links assemblages of glacial geomorphological features to particular styles of glaciation (Evans, 2003a), many of which have modern analogues that aid the interpretation of former glacial and climatic conditions. Following Clark (1999), glacial lineations were grouped into flow-sets according to parallel concordance, close proximity and similar morphometry, as well as relationship to ice marginal features such as moraines and meltwater channels. By mapping glacial landforms systematically and comprehensively, we were able to both reconstruct glacial limits and assess landsystem types and their palaeoglaciological implications based on landform suites.

127

128 **3.3 Proglacial lake reconstruction**

The reconstruction of former proglacial lakes can yield information on the relative position of ice lobes and their dynamics. Following Stokes & Clark (2004) and Lovell et al. (2012), we modelled proglacial lake formation using a Digital Elevation Model (DEM), constructed from ca. 90 m resolution SRTM data for areas of land, and ca. 900 m resolution ETOPO data for submarine areas that may have been previously exposed. The DEM was filled in 10 m increments to examine where lakes developed and over-spilled in relation to former shorelines and ice margins. The DEM data is sufficient for a regional-scale assessment of where lakes were likely to have developed (cf. Lovell et al., 2012), but the coarser resolution of the ETOPO data means that over-spill channels beneath present sea-level may have

60

138 been missed, and a lack of bathymetric data for present-day lakes means that their exact
139 depths are unknown. Additionally, the DEM provides present-day land elevation and not that
140 during glaciation, when the mass of the Patagonian Ice Sheet would have depressed the
141 mountain range. This should be corrected for Glacio-Isostatic Adjustment (GIA), but the
142 resolution of global model output, such as ICE-5G (Peltier, 2004), is too coarse to be of use
143 for this purpose. Consequently, we reconstructed palaeolakes based on a contemporary
144 DEM, but with the caution that they are likely minimum estimates of lake depth because the
145 regional pattern of ice loading would have been to overdeepen slopes towards the west. The
146 presence of lakes predicted by the DEM analysis was cross-checked and, although the field
147 evidence is inherently fragmentary, we did not identify any obvious conflict between
148 predicted lake levels and the presence of raised shorelines in the glacial geomorphological
149 mapping.

150

151 **4 Glacial Landform Assemblages**

152 This section summarises the nature of the glacial landform assemblages in the study area.
153 The results are in the form of a map published in Darvill et al. (2014) and we now describe
154 and interpret the landform assemblages before discussing their palaeoglaciological
155 significance in section 5.

156 **4.1 Ice-marginal landforms**

157 **4.1.1 Moraine ridges**

158 The clearest moraine ridges in the study area are those of the Skyring and Otway lobes,
159 where numerous arcuate ridges are nested around the main depressions (Figure 2), marking
160 the point at which the lobes were flowing up the adverse slopes of overdeepenings onto
161 higher relief areas (Barr & Lovell, 2014). Similar moraines are found on the northern side of
162 the Magellan lobe, particularly across Primera Angostura (Figure 2), within ca. 10 km of

1
2
3 163 Bahía Inútil in the BI-SSb lobe (Figure 3), and in the Río Gallegos lobe depression. Smaller,
4
5 164 less distinctive ridges aligned perpendicular to former ice flow are often draped over other
6
7 165 glacial features within the central Magellan and BI-SSb lobes, such as on Punta Gente,
8
9 166 where ridges are draped over drumlinised terrain north of Porvenir (Bentley et al., 2005;
10
11 167 Figure 4). Likewise, in the centre of the BI-SSb depression, ridges can be seen draped over
12
13 168 both lineations and subdued moraine topography (Figure 3).

14
15
16 169 The ridges include terminal moraines (sharp-crested, arcuate ridges around the main
17
18 170 depressions) and recessional moraines or recessional push moraines (smaller, less
19
20 171 distinctive ridges perpendicular to ice flow and draping other features), although it is difficult
21
22 172 to distinguish their form based on morphology alone. Two exceptions are where we have
23
24 173 supplementary sedimentological evidence to support the landform data. A section through a
25
26 174 moraine in the BI-SSb lobe shows silts and sands that have been strongly faulted and folded
27
28 175 (Figure 5). Similarly, sediments within one of the moraine ridges in the Otway lobe show
29
30 176 faulted sands and gravels (Figure 6). The deformation of moraine sediments in this way is
31
32 177 indicative of proglacial glaciotectionism (Rotnicki, 1976; Aber, 1985; Aber et al., 1989; van
33
34 178 der Wateren, 1995), and we interpret the deformation to represent thrusting and folding
35
36 179 during active re-advances of the ice lobes (Oldale & O'Hara, 1984; Harris et al., 1997;
37
38 180 Williams et al., 2001; Evans & Twigg, 2002; Phillips et al., 2002, 2008b, 2008a), at least in
39
40 181 these two locations. The BI-SSb moraine contains deformed lacustrine silts, indicating that
41
42 182 the timing and extent of retreat and re-advance was sufficient to allow a proglacial lake to
43
44 183 accumulate. Our interpretation suggests that some of the moraine ridges may be part of
45
46 184 composite thrust complexes, similar to those reported around the Strait of Magellan
47
48 185 (Clapperton et al., 1995; Benn & Clapperton, 2000a, 2000b).

49
50
51 186

53
54
55
56
57
58
59
60

1
2
3 187 4.1.2 Hummocky terrain

4
5 188 Hummocky terrain is abundant within the BI-SSb lobe (Figure 3), but is also found in
6
7 189 association with the Magellan lobe (Figure 4). It consists of semi-rounded hills and hollows at
8
9 190 both smaller (e.g. ≤ 5 m relief) and larger (> 5 m relief) scales, with the smaller hummocky
10
11 191 terrain forming arcuate bands running parallel to moraine ridges. The hummocks are
12
13 192 predominantly irregular and chaotic and were classified as ‘irregular hummocky terrain’
14
15 193 (smaller hummocky terrain) and ‘kettle-kame topography’ (larger hummocky terrain) by
16
17 194 Darvill et al. (2014).

18
19
20 195 Hummocky terrain is typically associated with deposition of supraglacial debris (Boulton,
21
22 196 1972; Benn, 1992; Kjaer & Kruger, 2001; Johnson & Clayton, 2003; Schomacker, 2008),
23
24 197 although the transport pathway of debris resulting in this terrain is often conjectural (Evans,
25
26 198 2009, and references therein). We infer that the disorganised nature of the landform is
27
28 199 indicative of periods of ice stagnation and down-wasting during overall recession of the ice
29
30 200 lobes, leaving behind buried ice and resulting in topographic inversion of the terrain (Clayton,
31
32 201 1964; Boulton, 1972; Etzelmüller et al., 1996; Kjaer & Kruger, 2001; Schomacker, 2008).
33
34 202 More specifically, the organisation of hummocky terrain in arcuate bands has been
35
36 203 interpreted as the product of incremental stagnation (*sensu* Eyles, 1979; Bennett & Evans,
37
38 204 2012) in other lowland settings (e.g. Attig et al., 1989; Ham & Attig, 1996; Clayton et al.,
39
40 205 2001; Dyke & Evans, 2003; Evans et al., 2014), a process-form regime that could also apply
41
42 206 to the settings described here if the glacier lobes were episodically carrying large englacial
43
44 207 and supraglacial debris loads.

45
46
47 208 Bands of larger hummocky terrain mark the Primera Angostura and Segunda Angostura
48
49 209 limits of the Magellan lobe (Meglioli, 1992; Benn & Clapperton, 2000a, 2000b; Rabassa,
50
51 210 2008; Figure 2), but are seen most clearly as a double band on both the north and south
52
53 211 sides of the BI-SSb depression (Figures 1, 3, 7). This landform was described as ‘kettle and
54
55 212 kame topography’ by (Darvill et al., 2014), but the nomenclature is problematic given that
56
57 213 there is no sedimentary evidence for kames and similar features in North America have an
58
59
60

1
2
3 214 ambiguous origin (*sensu* Evans, 2009). Rather, we tentatively group the landform with
4
5 215 hummocky terrain and suggest that further sedimentary work is required to establish the full
6
7 216 nature of this geomorphology. The topography consists of chaotic hills surrounding rounded
8
9 217 hollows, and delimited by broad outwash plains. Darvill et al. (2015a) mapped a series of
10
11 218 erratic boulder trains along the southern edge of the BI-SSb lobe, two of which drape over
12
13 219 the larger hummocky terrain. A deep section through the inner band of the BI-SSb lobe (the
14
15 220 San Sebastián drift) shows two basal diamict units separated by outwash sands and gravels
16
17 221 (Figure 7). This implies that the ice lobe advanced to form the outer (Río Cullen) band first
18
19 222 before retreating into the BI-SSb depression and subsequently re-advancing.
20
21
22
23

223

224 4.1.3 Geometrical ridges

225 A large swath of strikingly linear cross-cutting ridges occurs north of Laguna Larga in the
226
227 central BI-SSb depression. These are regularly-orientated geometrical ridge networks
228
229 (*sensu* Bennett et al., 1996), described as 'regular hummocky terrain' by Darvill et al. (2014;
230
231 Figures 3B and 8). They comprise discontinuous, cross-cutting, conjugate paired ridges,
232
233 generally orientated perpendicular to former ice flow. Although long-regarded as the
234
235 remnants of crevasse-squeeze ridges, and also diagnostic of glacier surges in a
236
237 landsystems sense (Raedecke, 1978; Sharp, 1985; Bennett et al., 1996), such landforms
238
239 have since also been related to: a) active temperate glacier lobes, where they occur in
240
241 narrow concentric arcs in association with sawtooth style push moraines (Evans & Twigg,
242
243 2002; Evans et al., 2015); and b) ice stream shutdown, where they occur in narrow corridors
244
245 on palaeo-ice stream trunks (Evans et al., 2016). The spatial arrangement of the BI-SSb
246
247 geometrical ridge networks is identical to the wide arcuate zones of surge-related crevasse-
248
249 squeeze ridges found on modern glacier forelands, suggesting they may record a phase of
250
251 glacier surging by the BI-SSb lobe (see discussion).

4.2 Subglacial landforms

4.2.1 Glacial lineations

Lineations occur in association with all five ice lobes, but vary in morphology from low-relief flutings to prominent oval-shaped drumlins. For example, clusters of subdued flutings occur around Bahía Inútil (Raedecke, 1978; Figure 3), whilst large swaths of rounded drumlins are found in the Río Gallegos, Skyring, Otway and Magellan lobes. Of particular note are the fields consisting of hundreds of elongate drumlins that occur in the outermost part of the Río Gallegos lobe (Ercolano et al., 2004; Figure 9), around Laguna Cabeza del Mar in the Otway lobe (Clapperton, 1989; Benn & Clapperton, 2000b; Figure 10C) and on the eastern side of the Magellan Strait (Bentley et al., 2005; Lovell et al., 2012; Figure 4).

The precise genesis of glacial lineations is contentious, but it is generally agreed that they are subglacially streamlined landforms related to the deformation and/or erosion of a soft substrate by fast flowing glacier ice (Stokes et al., 2011). Hence, the lineations in our study area were probably formed by subglacial deformation of glaciofluvial deposits during advances of warm, wet-based ice (Clapperton, 1989; Benn & Clapperton, 2000b). Generally, the lineations are associated with ice marginal features, but a few dense swaths of drumlins occur in isolation from any apparent ice margin and show elements of convergence and divergence, most clearly in the area around Laguna Cabeza del Mar in the Otway lobe (Figure 2). Here, we suggest that the attenuated bedforms, parallel concordance and abrupt lateral margins of the lineation patterns are similar to those in areas of former rapidly flowing ice (Stokes & Clark, 1999, 2001; Evans et al., 2008; Lovell et al., 2012).

4.2.2 Subdued moraine topography

Subdued moraine topography consists of low, arcuate changes in relief (> 1 km wide), often over-printed by other moraine ridges or bands of smaller hummocky terrain. The features are difficult to observe clearly on the ground and are best picked-out as positive relief in SRTM

imagery or changes in vegetation in Landsat imagery. Subdued moraine topography is predominantly found in the centre of the BI-SSb lobe and is fragmented in a regular pattern north of Laguna Larga (Raedecke, 1978; Figure 3B).

The regular fracturing of subdued moraine topography north of Laguna Larga could represent linear en echelon deposits linked to crevassing (Raedecke, 1978). However, this is unlikely because the topography is draped by younger features such as moraine ridges, glacial lineations and smaller hummocky terrain. Another possibility is that the subdued moraine topography is similar to the 'traction ribs' inferred beneath modern ice masses (Sergienko & Hindmarsh, 2013) and palaeo-ice stream tracks in the southwestern Laurentide Ice Sheet. Given the similarity in orientation to moraine ridges, however, the most likely explanation is that this subdued topography resulted from ice-marginal moraines that were subsequently overridden and moulded subglacially, similar to landforms (overridden moraines) observed in Iceland (Krüger, 1994; Evans & Twigg, 2002; Evans & Orton, 2015; Evans et al., 1999; Evans, 2009; Evans et al., 2015).

280

4.2.3 *Irregular dissected ridges*

A series of disorganised ridges, in places intersected by meltwater channels, are found in association with the Skyring and Río Gallegos lobes, most prominently to the southeast of the large swath of drumlins oriented southeastward in the Río Gallegos lobe (Flow-set 1: FS 1; Figure 9). The origin of the features is unclear, although the largest group appears to be situated at the intersection between the former Río Gallegos and Skyring ice lobes.

We suggest that the Río Gallegos lobe advanced first into the area, creating a drumlin field and moraine ridges. Subsequently, the Río Gallegos lobe retreated and the Skyring lobe advanced over the drumlins and moraines, causing subglacial deformation that resulted in an irregular pattern of hills and meltwater channels. The stratigraphic order is indicated by meltwater from the Skyring lobe draining into the Río Gallegos depression.

1
2
3 292
4
5
6 293 **4.3 Glaciofluvial landforms**

7
8 294 **4.3.1 Meltwater channels**

9
10
11 295 The study area is dominated by meltwater features, including hundreds of sinuous channels.
12
13 296 In places, such as the outer moraines of the Skyring, Otway and Magellan lobes, the
14
15 297 channels flow between moraine ridges (Figure 2), but elsewhere, such as the BI-SSb
16
17 298 depression and inner parts of the Río Gallegos, Skyring, Otway and Magellan lobes,
18
19 299 meltwater channels are clearer than the associated moraines (Bentley et al., 2005). The
20
21 300 channels vary in size, from less than 50 m wide to more than 150 m wide, and are
22
23 301 sometimes associated with channels of outwash where ice overtopped topographic
24
25 302 constraints (e.g. northeast of the Skyring and Otway lobes or north of the BI-SSb lobe).

26
27
28 303
29
30
31 304 **4.3.2 Outwash plains**

32
33 305 Outwash plains were identified based on their relatively smooth, featureless appearance,
34
35 306 whose surfaces gently grade downslope from former ice margins. The plains are associated
36
37 307 with moraines and hummocky terrain in all of the ice lobes, and (where they are
38
39 308 unconstrained by topography) wide, open sandur plains grade eastward. A prominent
40
41 309 exception is the outwash plain originating from Laguna Blanca in the Skyring lobe (Figures 2
42
43 310 and 10), which trends south-eastward into the Strait of Magellan and surrounds a former
44
45 311 moraine belt associated with the Otway lobe (Lovell et al., 2012).

46
47
48 312 The extensive nature of the glaciofluvial features implies that all of the ice lobes produced
49
50 313 large quantities of meltwater during stillstands and retreat. Whilst meltwater channels and
51
52 314 outwash plains are abundant within the study area, features such as ice contact fans, pitted
53
54 315 outwash plains and eskers are not. Indeed, there is a notable absence of eskers associated
55
56 316 with the ice lobes, which might imply that meltwater was rarely routed into conduits at the

bed (perhaps draining into the substrate or maybe as a result of cold-based ice) or that there was insufficient time for conduits to form (Storror et al., 2014a, 2014b). Alternatively, ice-walled deposition may have been restricted to englacial settings, in a similar fashion to the receding lowland lobes of Iceland, where drainage bypasses overdeepenings and hence eskers emerge on the surface of downwasting snouts (Spedding & Evans, 2002; Bennett et al., 2010; Bennett & Evans, 2012). Such a scenario would result in tunnel fills being significantly reworked during deglaciation and consequently difficult to identify in the landform record.

325

4.4 Proglacial lake landforms

4.4.1 Former shorelines

Numerous fragmentary shorelines are found within ca. 10 m elevation of contemporary coastal areas. In addition, continuous shorelines are found above 10 m and, further inland, around Lago Balmaceda in the Río Gallegos lobe (Figure 1); Seno Skyring; Seno Otway (Figure 2); Laguna Blanca in the Skyring lobe (Figure 10A); south of Primera Angostura in the Strait of Magellan (Figure 4); and Bahía Inútil (Figure 3A). Whilst the Skyring, Otway, Magellan and Bahía Inútil shorelines are generally within 30 m of present-day sea-level, those around Lago Balmaceda and Laguna Blanca are substantially higher.

Our glacial reconstruction, combined with DEM modelling, and the occurrence of localised palaeolacustrine sedimentary evidence, leads us to infer that these shorelines relate to a total of six large proglacial lakes that existed at various times in the overdeepenings in front of the former ice lobes. This reconstruction supports previous work on proglacial lake reconstruction in the area (Porter et al., 1992; Clapperton et al., 1995; McCulloch et al., 2005a; Sagredo et al., 2011; Stern et al., 2011; Lovell et al., 2012; Kilian et al., 2007, 2013). The ice-marginal truncation of these shorelines suggests that they formed in front of the ice lobes, likely during recession into their respective topographic basins/overdeepenings.

5 Style and dynamics of Quaternary glaciation

5.1 Active temperate glacial landsystem

The majority of the glacial geomorphology in the study area can broadly be divided into three landform assemblages: morainic, subglacial and glaciofluvial (Figure 11). The components of each assemblage as well as their inter-relationships are consistent with an active temperate glacial landsystem developed during the advance and retreat of the ice lobes (Evans & Twigg, 2002). The warm-based active recession of this landsystem produces three characteristic landform-sediment associations. Firstly, dump, push and squeeze moraines composed of proglacial sediments mark the ice limit, sometimes displaying annual signatures or evidence for stillstands that create stacked features (Price, 1970; Evans et al., 1999; Evans & Twigg, 2002; Evans et al., 2015). Low amplitude ridges formed from overridden push moraines may also be found, draped by glacial lineations and moraines. Secondly, subglacially streamlined flutings and drumlins occur between these moraines. Thirdly, extensive glaciofluvial landforms occur where meltwater flows away from the warm-based ice front. These features include ice-contact and spillway-fed outwash fans; ice marginal outwash tracts; kame terraces; pitted outwash and eskers (Evans & Twigg, 2002; Evans, 2003b). Active temperate glaciers are also capable of constructing arcuate bands of hummocky moraine during recession as a result of incremental stagnation, driven by pulses of supraglacial debris (Eyles, 1979; Bennett & Evans, 2012). The geomorphology in the central part of the BI-SSb lobe (Figure 11) displays many of the landforms associated with an active temperate landsystem: moraines containing proglacially-thrusted and folded sediments; possible recessional push moraines; overridden moraines; flutings and drumlins; and glaciofluvial meltwater channels and outwash plains.

The similarity between the landform assemblages in our study area and those associated with active temperate glaciers supports the assertion that the ice lobes dominantly operated

under an active temperate glacial landsystem. This is especially clear in the geomorphology of the central BI-SSb lobe. The other ice lobes show the characteristics associated with active temperate glaciers, but the geomorphology is either not as well preserved (as in the Río Gallegos and Magellan lobes) or the moraines are more tightly nested (as in the Skyring and Otway lobes) so that the assemblages are not as clear. Tightly nested moraine sequences may indicate that the Skyring and Otway lobes retreated more slowly than the other ice lobes, although there are no chronological constraints on the rate of this recession (see Section 6.2). Similar patterns of tightly nested features have been observed in Iceland (Bradwell et al., 2013), but, in our study, the cause may be related to topographic constraints, rather than annual cycles in retreat (Kaplan et al., 2009; Anderson et al., 2012; Barr & Lovell, 2014). Hence, the landform assemblages of the Skyring and Otway lobes may be indicative of an active temperate landsystem, but they are not as clear as the BI-SSb lobe due to slower glacier recession.

5.2 External forcing of glacier behaviour

There are a number of implications associated with our interpretation of an active temperate glacial landsystem. Principally, Benn & Clapperton (2000a, 2000b) suggested that the Magellan lobe operated under subpolar conditions, with a cold-based margin, during the gLGM. By contrast, Bentley et al. (2005) advocated warm-based conditions extending to the ice margin based on different glacier limits that implied steeper ice surface gradients. The presence of proglacially thrust moraines and arcuate bands of hummocky terrain, if they originated as controlled ridges (*sensu* Evans, 2009), are consistent with cold-based ice or at least a polythermal basal regime (Benn & Clapperton, 2000b; Evans, 2009). Evidence for glacial lineations extending to individual moraine ridges is a landform association indicative of warm-based ice throughout the snout (Evans & Twigg, 2002; Evans, 2003b), and arcuate hummocky terrain bands set within recessional push moraines are consistent with phases of incremental stagnation by temperate glaciers. However, glacial thermal regimes form a continuum upon which the landsystem signatures of polythermal glaciers, with frozen snouts

59
60

(e.g. Svalbard valley glaciers and Icelandic upland icefields), and active temperate glaciers, with winter frozen toe zones and pulsed supraglacial debris transfer, would be difficult to differentiate (Evans, 2009). Particularly significant for southernmost Patagonia is the independent evidence for permafrost conditions at the gLGM (Benn & Clapperton, 2000a, 2000b; Bockheim et al., 2009). Therefore, we suggest that the former ice lobes were predominantly active temperate in nature, but were subject to periods of polythermal conditions, thereby giving rise to phases of controlled moraine construction. A similar scenario has been proposed for the southern limits of the Laurentide Ice Sheet in the interior plains of North America (Clayton et al., 2001; Colgan et al., 2003; Bauder et al., 2005; Evans et al., 2006, 2014). This further illustrates the importance of recognising what Evans (2013) identifies as landsystem superimposition and spatio-temporal change, whereby changes in the climatic environment occupied by a glacier will inevitably be reflected in its geomorphic signature. The incremental stagnation versus controlled origin of the hummocky terrain arcs is important to the palaeoglaciological reconstruction and its palaeoclimatic inferences made above, and therefore needs to be vigorously tested by future sedimentological investigations.

The complex landform-sediment signatures of the southernmost Patagonian outlet lobes are indicative of active temperate glaciers. Such glaciers are characterised by active advance during periods of overall recession, primarily controlled by regional climatic variability (Colgan et al., 2003; Evans, 2003b, 2011; Evans & Orton, 2015; Evans et al., 2015). Modern examples include Breiðamerkurjökull, Fjallsjökull, Heinabergsjökull, Skálafellsjökull and Fláajökull in Iceland (Evans & Twigg, 2002; Evans et al., 2015; Evans & Orton, 2015; Evans, 2003b). Both topographic control (Kaplan et al., 2009; Anderson et al., 2012; Barr & Lovell, 2014) and internal ice dynamics (Benn & Clapperton, 2000a, 2000b; Lovell et al., 2012) have also been proposed as factors controlling glacial activity within this region. Our geomorphological evidence implies that, for the majority of ice fluctuations, these internal forcing factors may have been of secondary importance to climatic variability.

5.3 Internal forcing of glacier behaviour

Whilst the landform evidence suggests that the ice lobes predominantly advanced and retreated according to an externally-forced active temperate landsystem, there is also evidence for periods of rapid ice flow and proglacial lake development. Both of these situations may have temporarily interrupted the primary climatic driver of glacial activity.

5.3.1 Transient rapid ice flow

A large swath of elongated, closely-spaced drumlins in the inner part of the Otway lobe around Laguna Cabeza del Mar (FS 8 in Figure 12) has previously been hypothesised to represent rapid ice flow (Benn & Clapperton, 2000b; Lovell et al., 2012). Unlike other glacial lineations in the study area, this drumlin field resembles a terrestrial palaeo-ice stream, with convergent flowlines, attenuated bedforms and abrupt lateral margins (Stokes & Clark, 1999; Clark & Stokes, 2003; Lovell et al., 2012). Additionally, Lovell et al. (2012) raised the possibility for surge-like behaviour of the Otway lobe based partly on this landform evidence. Our study confirms that many of the landforms associated with surging activity are exhibited in the study area, including thrust moraines, highly elongate flutings, hummocky terrain and crevasse-squeeze ridges, which are often viewed as diagnostic of surge activity (Evans & Rea, 1999, 2003; Schomacker et al., 2014; Lovell et al., 2015). As such, we suggest the ice lobes may have periodically displayed rapid ice-flow and possible surge-like behaviour.

Our reconstruction of fast-flowing ice would have affected ice dynamics in parts of the ice lobes. Similar fast-flowing systems in northern Patagonia during the gLGM are hypothesised to have resulted in greater ice discharge rates (Glasser & Jansson, 2005), and rapid ice flow across much of the eastern portion of the Patagonian Ice Sheet may help to explain mismatches between model outputs and landform reconstructions (Hulton et al., 2002; Glasser & Jansson, 2005). The presence of landforms linked to possible surge-like advances further implies that, at times, the ice lobes may have briefly advanced in response to non-climatic forcing. The possible evidence for palaeo-surges warrants further research,

449 particularly given the paucity of examples of surging systems in the palaeo-record and the
450 fact that some contemporary active temperate glaciers, such as Breiðamerkurjökull, have
451 also displayed surging activity and this is recorded in landsystem overprinting (Evans &
452 Twigg, 2002).

453

454 5.3.2 Proglacial lake development

455 The clearest proglacial lake landforms are within the Skyring lobe, where meltwater
456 accumulated above the present day Laguna Blanca. Shorelines and DEM modelling indicate
457 a maximum lake surface elevation of ca. 190 m.a.s.l., which drained northward into the basin
458 previously occupied by the Río Gallegos lobe (Lovell et al., 2012; Figure 10A and B). This
459 reconstruction is supported by sedimentological evidence northeast of Laguna Blanca
460 consisting of rhythmically laminated silt and clay sediments, containing dropstones (Figure
461 10E). Our ice limit for the Otway lobe differs from Lovell et al. (2012), such that a similar
462 proglacial lake did not form in front of the Otway lobe because meltwater could drain
463 southeastward in front of the Magellan lobe. Once the Skyring lobe retreated beyond the
464 topographic bluff separating it from the Otway lobe, drainage of the palaeo-Laguna Blanca
465 proglacial lake switched from a northward to a south-eastward direction, in front of the Otway
466 and Magellan lobes and into the Strait of Magellan (Figure 10C and F). The drainage
467 resulted in the formation of large meltwater channels and an associated outwash plain that
468 surrounded a moraine belt associated with the Otway lobe.

469 Proglacial lakes are also reconstructed in front of the BI-SSb and Magellan lobes (Figure
470 13), consistent with the presence of lacustrine sediments (McCulloch et al., 2005a). The BI-
471 SSb lake reached approximately 20 m.a.s.l. before draining at Onaisín, eastward toward the
472 Atlantic through a channel now marked by Laguna Larga (Figure 3A and B). Likewise the
473 Magellan lake drained eastward toward the Atlantic, but the height of the lake is less clear as
474 the drainage channel is below present day sea-level (Porter et al., 1992; Clapperton et al.,

1995; McCulloch et al., 2005a). Our reconstruction suggests that at its peak the lake extended onto the low plain in front of the Otway lobe. Small lakes also formed at 10-20 m.a.s.l. on the eastern flank of the Magellan lobe, north of Porvenir (Figure 4B). One of these lakes deposited a large section of rhythmically laminated silt and clay sediments at Laguna Verde (Figures 10G, H, I and 4B).

A proglacial lake formed in front of the Otway lobe once ice had retreated into the present-day Seno Otway, and there is evidence for a channel initially draining north-eastward into the Strait of Magellan (Mercer, 1976; McCulloch et al., 2005a). However, once the lake level dropped to around 20 m.a.s.l., drainage would have switched to the northwest through Canal Fitzroy into a similar lake at 10-20 m.a.s.l. within present-day Seno Skyring (Figure 2). The Skyring proglacial lake drained northward through Estero Obstrucción (Figure 1) into a large lake in front of the Río Gallegos lobe, the extent of which is unclear (Sagredo et al., 2011; Stern et al., 2011), although final drainage of the Otway, Skyring and Río Gallegos lakes would have been westward through Golfo Almirante Montt (Figure 1) once ice had receded into the mountains (McCulloch et al., 2005a; Stern et al., 2011).

Former proglacial lakes would also have affected glacial dynamics by promoting increased rates of ice retreat (Porter et al., 1992; Teller, 2003; Lovell et al., 2012; Carrivick & Tweed, 2013). The presence of a proglacial lake at the margin of a glacier can trigger positive feedbacks such as increased englacial water pressure and temperature; increased subglacial pressure; and increased ice surface gradients, which can result in calving, ice-margin flotation and the flushing of sediment from beneath the ice (Carrivick & Tweed, 2013). This results in greater ice mass loss and glacial draw-down (Lovell et al., 2012). Porter et al. (1992) also suggested that calving of the Magellan and BI-SSb lobes could have resulted in a rapid loss of ice. Given the potential importance of proglacial lakes in controlling ice dynamics within this region, future work should aim to better constrain their evolution over time.

6 Glacial reconstruction and timing

6.1 Glacial limits and flow-sets

Three sets of ice-marginal landforms were used to demarcate former glacial limits: morainic landforms (including hummocky terrain), glacial lineation flow-sets (see below), and meltwater channels. The different lines of evidence yielded a consistent pattern and the data were synthesised to create a map of prominent limits for each ice lobe (Figure 12). Many of these limits corroborate previous work defining glacial limits in the region (Meglioli, 1992; Clapperton et al., 1995; Coronato et al., 2004; Bentley et al., 2005; Lovell et al., 2012), but the wider scope of our mapping reveals a more detailed pattern than has been previously reported. For comparison, we also included less extensive limits from Kilian et al. (2007) for the Skyring lobe (Figure 12D).

A total of 20 flow-sets (FS) were identified within the study area (Figure 12B), with those of the Skyring and Otway lobes similar to Lovell et al. (2012). An exception is the separation of FS 7 and 8 based on differing morphology: the drumlins around Laguna Cabeza del Mar are noticeably longer, wider, and higher than the long flutings further to the northeast. This division is important because FS 8 corresponds with moraines dissecting the Otway depression. Some flow-sets within the inner parts of the Río Gallegos, Skyring, Magellan and BI-SSb lobes have been discussed in previous studies (Benn & Clapperton, 2000b; Ercolano et al., 2004; Bentley et al., 2005; Lovell et al., 2012), but the outer flow-sets of the Río Gallegos and BI-SSb lobes have not been reported previously.

The glacial limits that we have defined can be used to reconstruct a relative sequence of events in the glacial history, enhanced by information about ice dynamics from our landsystems approach. Correlating between the limits of adjacent ice lobes can be problematic because they are generally reconstructed from fragmentary records, and joining-up limits can over-emphasise correlation without robust chronological controls. However, in places, our approach informs the relative timing of advance and retreat between lobes based

on cross-cutting landform assemblages. Using cross-cutting relationships between flow-sets and ice marginal landform assemblages, we identify eight separate relative time steps in our reconstruction (Figure 13). These time steps are shown in relation to present-day basal topography and the height of former proglacial lakes in Figure 14. We now briefly discuss key aspects of the nature and timing of this glacial history in relation to the eight time steps and a compilation of recalibrated chronological information (Figure 15).

6.2 Chronological framework

This study is principally engaged with reconstructing the dynamics of former ice lobes without considering time-dependent variation. However, it is possible and informative to place our time steps within a framework of previously published chronological data (Figures 13 and 15). Full details of this chronological compilation, including calibration and recalculation methods, are given in the Supplementary Material and Tables S1, S2, S3 and S4.

6.2.1 Time steps 1-4: Pre-gLGM advances

There is uncertainty regarding the ages of pre-gLGM glacial limits within the study area (time steps 1-4 in our reconstruction). Cosmogenic nuclide exposure dating of boulders from moraines of the BI-SSb, Magellan and Río Gallegos lobes (Kaplan et al., 2007; Evenson et al., 2009) has yielded ages that are substantially younger than associated $^{40}\text{Ar}/^{39}\text{Ar}$ dates from nearby volcanic flows (Figure 13A, B and C; (Meglioli, 1992; Singer et al., 2004), the cause of which is contentious (Kaplan et al., 2007; Darvill et al., 2015a). Darvill et al. (2015b) used $^{10}\text{Be}/^{26}\text{Al}$ depth profiles through outwash sediments to show that two limits previously assigned to older glacial stages were deposited during the last glacial cycle. Overall, the large spread of boulder ages associated with time steps 1-4 may result from post-depositional processes such as boulder erosion (Kaplan et al., 2007) and the gradual melt-out of dead ice in hummocky terrain (Schomacker, 2008; Darvill et al., 2015a).

In time step 4, the BI-SSb lobe re-advanced to close to the limit of time step 3 (Figure 14), with ^{10}Be dates from boulders of 24.3 ka and 224.1 ka (Figures 13D; Kaplan et al., 2007). A depth-profile through associated outwash yielded a more robust age of 30.1 ka (Darvill et al., 2015b). For the Magellan lobe, eight ^{10}Be ages between 24.8 ka and 36.9 ka and two ^{26}Al ages of 31.0 ka and 32.6 ka (Kaplan et al., 2007) imply that the limit may have been deposited at a similar time to that of the BI-SSb lobe (Figure 15).

6.2.2 Time steps 5-6: Re-advances, rapid flow and lake drainage

The Otway lobe re-advanced significantly during time step 5 (Figure 13E), forming FS 8 around Laguna Cabeza del Mar and shifting the ice divide between the Otway and Magellan lobes south-eastward into the present-day Strait of Magellan. The BI-SSb lobe also re-advanced to a limit close to Bahía San Sebastián, depositing a large terminal moraine that is still preserved east of Laguna Larga (Figure 3) and forming FS 17 (Figure 13E). The re-advances of these two ice lobes may have been in response to rapid ice flow (and possible surge-like activity based on the presence of thrust moraines, highly elongate flutings, hummocky terrain and crevasse-squeeze ridges). The Río Gallegos, Magellan and Skyring lobes retreated during time step 5, with the latter developing a proglacial lake – palaeo-Laguna Blanca – which may have further facilitated ice loss through calving (Figures 13E and 14). However, there are no direct age constraints for this time step. Recession continued during time step 6, allowing the potentially catastrophic drainage of palaeo-Laguna Blanca from in front of the Skyring lobe east to south-easterly in front of the Otway and Magellan lobes (Figure 13F). The drainage event is important because it acts as a stratigraphic tie-point for all three ice lobes (Figure 15). As mentioned in Section 6.2.1, ages of 24.8 ka and 36.9 ka for the Magellan lobe at Primera Angostura (Figure 2) suggest that it advanced prior to the gLGM during the last glacial cycle. The lake drainage is constrained by these ages and four more ^{10}Be ages of 27.4 ka to 29.9 ka on Península Juan Mazía (McCulloch et al., 2005b; Kaplan et al., 2008a). The implication is that the Skyring, Otway

578 and Magellan lobes were all retreating from more extensive positions prior to the gLGM
579 (Figure 15).

580 6.2.3 Time step 7: The gLGM

581 During time step 7, the ice lobes reached positions that have been broadly correlated with
582 the gLGM (Figures 13G and 15). Based upon our landform evidence (e.g. highly elongate
583 flutings and hummocky terrain), the Magellan lobe readvance may have been surge-like, and
584 has been ^{10}Be dated to between 18.3 ka and 23.2 ka. The BI-SSb lobe readvance has also
585 been ^{10}Be , ^{26}Al and ^{36}Cl dated to between 15.6 ka and 55.8 ka (though sixteen ^{10}Be dates
586 were between 17.6 ka and 24.9 ka; McCulloch et al., 2005b; Kaplan et al., 2007, 2008a;
587 Evenson et al., 2009). The reason for the scatter in ages is unclear, although the ^{10}Be date
588 of 55.8 ka may be due to inheritance, given that most of the dates are from a large erratic
589 boulder train on the south-eastern side of Bahía Inútil (Darvill et al., 2015a). There are no
590 supporting ages for the Río Gallegos, Skyring and Otway lobes but they were likely situated
591 within the present-day fjords.

592 6.2.4 Time step 8: Rapid retreat

593 All of the ice lobes were in post-gLGM retreat during time step 8 (Figure 13H), developing
594 proglacial lakes in front of their receding margins that likely increased the rate of ice loss
595 through calving (Figure 14; Porter et al., 1992; Kilian et al., 2007; Carrivick & Tweed, 2013).
596 The Magellan and BI-SSb proglacial lakes drained eastward toward the Atlantic, although
597 their extent is uncertain. Drainage of the Otway proglacial lake initially occurred east to
598 north-eastward into the Magellan lake, but as lake levels dropped during ice retreat,
599 drainage switched to north-westward into the Skyring proglacial lake, cutting the Fitzroy
600 channel (McCulloch et al., 2005a; Kilian et al., 2013). In turn, the Skyring proglacial lake
601 drained into the Río Gallegos proglacial lake that, by this time, may have drained westward
602 into the Pacific Ocean through ice-free fjords dissecting the Andes (McCulloch et al., 2005a;
603 Kilian et al., 2013). It is possible that Río Gallegos ice was still extensive, such that drainage

604 occurred in a southwards direction, reaching the Pacific through Seno Otway (Stern et al.,
605 2011). Ultimately, uncertainty in the configuration of the Río Gallegos lobe makes it difficult
606 to assess drainage routes.

607 Ice-free conditions in Seno Skyring and Seno Otway have been dated to at least 14.8 ka and
608 14.7 ka, respectively, based on radiocarbon dating and tephrostratigraphy of sediment cores
609 (Kilian et al., 2013). The Skyring lobe may have been undergoing rapid retreat linked in part
610 to calving (Kilian et al., 2007). Numerous radiocarbon dates suggest that retreat of the
611 Magellan and BI-SSb ice lobes was also under way by at least 14-15 ka (Porter et al., 1992;
612 Anderson & Archer, 1999; Clapperton et al., 1995; McCulloch & Bentley, 1998; McCulloch et
613 al., 2005b), although the presence of the Reclús tephra within lake sediments implies that
614 full retreat and final proglacial lake drainage cannot have been before *ca.* 14.3 ka
615 (McCulloch et al., 2005a). The rapid retreat, and possible collapse, of the BI-SSb lobe is
616 supported by radiocarbon dates as early as 16.8 ka in central Cordillera Darwin (Hall et al.,
617 2013; Figure 15). A similarly rapid retreat is reconstructed for the Magellan lobe (Figure 15),
618 likely linked to the broad calving termini of these ice lobes (Porter et al., 1992).

619

620 **7 Conclusions**

621 This study presents a reconstruction of the relative history of five former ice lobes in
622 southernmost South America. We reconstruct eight time steps, which highlight the dynamic
623 nature of this part of the ice sheet margin, and use a landsystem approach to show that the
624 ice lobes dominantly displayed behaviour similar to active temperate glaciers. This involved
625 warm-based ice actively re-advancing during overall retreat of the ice margin and questions
626 previous hypotheses that the ice lobes displayed sub-polar characteristics with cold-based
627 margins. The implication is that active temperate ice lobes would have been primarily
628 controlled by regional climate variability. Superimposed on these active temperate
629 landsystems are areas where swaths of elongated, closely-spaced drumlins and suites of

landforms including possible crevasse-squeeze ridges suggest periodically rapid ice flow, perhaps indicative of some readvances linked to surge-like activity. Additionally, our reconstruction highlights the importance of the palaeo-Laguna Blanca proglacial lake, which developed in front of the Skyring lobe, and drained, potentially catastrophically, prior to the gLGM. The development of other proglacial lakes in front of all of the ice lobes following the gLGM would have promoted calving and rapid retreat, or collapse, of the ice margins.

For the Río Gallegos, Skyring and Otway lobes, existing age constraints are scarce and contradictory, but our recalculation of dates for older positions of the Magellan lobe suggests that at least one limit of greater extent than the gLGM limit was deposited around 30 ka. This suggests that the BI-SSb and Magellan lobes advanced in a similar manner and at similar times. Similarity in the timing of ice advances from the available chronological information implies that, broadly speaking, ice lobe response was primarily controlled by climate variability, supporting a model of active temperate glaciation. However, additional chronological controls are needed to test this model further, particularly for the Río Gallegos, Skyring and Otway lobes.

3 996 **10 Figure captions**

4
5
6 997 Figure 1. (A) Location of the study area in southern South America. (B) Overview of the
7 998 geomorphological map from Darvill et al. (2014) showing the locations of figures and
8 999 locations mentioned in the text. (C) Stylised representation of the southernmost part of the
9 1000 former Patagonian Ice Sheet, highlighting the five former ice lobes discussed in this paper.
10 1001 The approximate position of the ice divide is based on Hulton et al. (2002), but is shown for
11 1002 illustrative purposes only.

12
13
14 1003 Figure 2. An overview of the glacial geomorphology relating to the Río Gallegos, Skyring,
15 1004 Otway and Magellan lobes, including key locations mentioned in the text (location shown in
16 1005 Figure 1).

17
18 1006 Figure 3. (A) Overview of the glacial geomorphology associated with the centre of the BI-
19 1007 SSb lobe (location shown in Figure 1). Note the spillway marked by former shorelines
20 1008 associated with a proglacial lake that drained at Onaisín through Laguna Larga. (B)
21 1009 Enlargement of the central part of (A) showing cross-cutting relationships between subdued
22 1010 moraine topography and moraine ridges, glacial lineations and smaller hummocky terrain.
23 1011 (C) Enlargement of (B) showing the ordered nature of the regular hummocky terrain mini-
24 1012 ridges and the cross-cutting relationships more clearly.

25
26
27 1013 Figure 4. (A) Overview of the glacial geomorphology associated with the Magellan lobe
28 1014 (location shown in Figure 1). Península Juan Mazía may have been the terminus of a surge-
29 1015 like advance (see text). (B) Enlargement of Punta Gente and the large field of elongate
30 1016 drumlins, in places draped by small moraine ridges.

31
32 1017 Figure 5. Sketch log (A) and accompanying photographs (B and C) of proglacially tectonised
33 1018 lacustrine silts and sands within an end moraine of the BI-SSb lobe (location shown in Figure
34 1019 3A). There is a high degree of folding and faulting. The large section suggests that the ice
35 1020 lobe retreated sufficiently for a sizeable proglacial lake to develop, prior to re-advance.

36
37
38 1021 Figure 6. Sketch log (A) and accompanying photographs (B and C) of a glaciectonised
39 1022 moraine associated with re-advance of the Otway lobe (location shown in Figure 2). The
40 1023 normal thrust faults are particularly highlighted by a deformed tephra layer in (C). The
41 1024 sediments are characteristic of outwash material that was likely deposited during retreat of
42 1025 the ice prior to re-advance and proglacial thrusting.

43
44 1026 Figure 7. (A) A Google Earth image of larger irregular hummocky terrain from the south side
45 1027 of the BI-SSb lobe. (B) Field photograph of the hummocky topography on the north side of
46 1028 the BI-SSb lobe, illustrating the rounded hills and lakes. (C) A section through the inner band
47 1029 of larger hummocky terrain on the north side of the BI-SSb lobe. The top unit relates to this
48 1030 inner glacial limit (the San Sebastián drift), but overlies an earlier diamict unit and associated
49 1031 outwash (the Río Cullen drift), indicating that the ice lobe re-advanced (person for scale).

50
51
52 1032 Figure 8. (A) A Google Earth image of regular hummocky terrain from the centre of the BI-
53 1033 SSb lobe (location shown in Figure 3B). This terrain resembles geometrical ridge networks
54 1034 and could be preserved crevasse-squeeze ridges. To illustrate this, (B) shows a Microsoft
55 1035 Bing Maps image of crevasse-squeeze ridges in front of the surging Brúarjökull glacier in

1036 Iceland. Note that although the glaciers in question are markedly different in size, the images
1037 are at the same scale.

1038 Figure 9. Glacial geomorphology found at the intersection between the Río Gallegos and
1039 Skyring lobes (location shown in Figure 2). (1) to (4) show a stylised formation mechanism
1040 for the irregular dissected ridge features. (1) The Río Gallegos advances first, creating a
1041 swath of drumlins (2), and possibly moraines, that are later overridden by an advance of the
1042 Skyring lobe (3). The order is dictated by the flow of meltwater from the Skyring lobe into the
1043 Río Gallegos basin (4).

1044 Figure 10. Evidence for proglacial lakes within the study area. (A) shows the geomorphology
1045 and (B) the reconstructed ice limit and palaeo-Laguna Blanca proglacial lake just prior to
1046 drainage, when discharge flowed northwards. (C) The geomorphological evidence for lake
1047 drainage eastward into the Strait of Magellan once the Skyring lobe retreated beyond the
1048 bluff separating it from the Otway lobe (locations shown in Figure 2). (D) Raised shorelines,
1049 (E) laminated lake sediments with a dropstone circled, and (F) a drainage channel
1050 associated with palaeo-Laguna Blanca (locations shown in A and B). (G) Rhythmically
1051 laminated sediments from Laguna Verde (see Figure 4 for location). (H) Enlarged part of (G)
1052 showing several heavily deformed layers, possibly due to earthquake-induced tectonisation.
1053 (I) Dropstones are found within the Laguna Verde sequence (circled).

1054 Figure 11. Glacial geomorphology of (A) the BI-SSb lobe and (B) the Río Gallegos, Skyring,
1055 Otway and Magellan lobes. The geomorphology has been grouped and re-coloured
1056 according to the three dominant landform suites indicative of an active temperate glacial
1057 landsystem.

1058 Figure 12. (A) Simplified version of the glacial geomorphology in the study area to show the
1059 dominant ice flow and ice marginal features. (B) The flow-sets defined in this study (FS 1-
1060 20). (C) The dominant limits associated with four different sets of ice-marginal features.
1061 These were synthesised into glacial limits, shown in (D). The two innermost limits of the
1062 Skyring lobe are from Kilian et al. (2007). Eight of these limits are used in our glacial
1063 reconstruction time steps, coloured according to Figure 14.

1064 Figure 13. Reconstructed glacial history for the five ice lobes studied, with eight time steps
1065 shown in (A) to (H). The hypothesised ice divide based on Hulton et al. (2002) is shown in
1066 (A) and (B) for reference. We show the rest of the ice sheet for completeness, with
1067 hypothesised gLGM limits based on Coronato et al. (2004). The rest of the ice sheet would
1068 have retreated over time, but that was not part of our study. Also shown in (A) and (B) are
1069 hypothesised drainage divides between the five ice lobes (bold dashed black lines) and the
1070 lines of topographic profiles for each ice lobe shown in Figure 14 (fine dashed black lines).
1071 Key flow-sets are shown and blue arrows show the direction of lake drainage routes.
1072 Question marks show where the ice configuration is unknown and black arrows in (H) show
1073 final retreat during time step 8. Published chronological data are shown where appropriate
1074 (see text for discussion). These are: argon dates (red text/circles); cosmogenic nuclide
1075 exposure dates (yellow circles) consisting of recalibrated ^{10}Be dates (black text), recalibrated
1076 ^{26}Al dates (italic blue text) and ^{36}Cl dates (italic green text); and cosmogenic nuclide depth
1077 profiles (bold black text/circles).

1
2
3 1078 Figure 14. Topographic profiles for each ice lobe, shown as changes in elevation relating to
4 1079 present-day sea-level against distance from the hypothesised ice sheet divide. Ice flowed
5 1080 from left to right. The profiles from the ice divide to the outermost time step are shown in
6 1081 Figure 13A and B. The coloured numbers relate to the time steps shown in Figure 13D.
7 1082 Present-day sea-level is shown (short dashes), as well as the approximate sea-level at the
8 1083 gLGM (long dashes). Hence, the outermost limits of the BI-SSb lobe were in the Atlantic
9 1084 Ocean but would have formed on the exposed continental shelf. Also shown are the
10 1085 approximate heights of former proglacial lakes. The Río Gallegos lake would have dropped
11 1086 progressively over time, but the timing is not well constrained.

12
13
14 1087 Figure 15. A distance-time graph for the five ice lobes over the last glacial cycle, based on
15 1088 cosmogenic nuclide and radiocarbon dating discussed in the text. Dated lava flows suggest
16 1089 that most of the ice lobes would have advanced during earlier glacial cycles (Meglioli, 1992;
17 1090 Singer et al., 2004; Kaplan et al., 2007). The BI-SSb lobe contains a large number of dates,
18 1091 but with scattered ages and large associated errors. It is not possible to reconcile the
19 1092 cosmogenic nuclide ages and some of the radiocarbon dates during deglaciation. The
20 1093 Magellan lobe contains fewer dates, but a more consistent ice-retreat history. The Otway
21 1094 and Skyring lobes contain few dates, but must have been retreating from a limit prior to *ca.*
22 1095 30 ka because of the lake drainage from palaeo-Laguna Blanca in front of the Skyring,
23 1096 Otway and Magellan lobes (the blue stratigraphic correlation bar). Note the similarities in the
24 1097 glacial histories of these four ice lobes, including retreating from extensive positions prior to
25 1098 30 ka and the gLGM, and rapid late-stage retreat. The timing of advance and retreat of the
26 1099 Río Gallegos lobe is not well constrained, partly because many of the cosmogenic nuclide
27 1100 and radiocarbon dates are from lateral positions that cannot be robustly linked to the former
28 1101 ice terminus. A large number of radiocarbon dates are shown from (Sagredo et al., 2011),
29 1102 but these cannot be tied to the ice terminus and are simply shown against the approximate
30 1103 ice distance in time step 7.

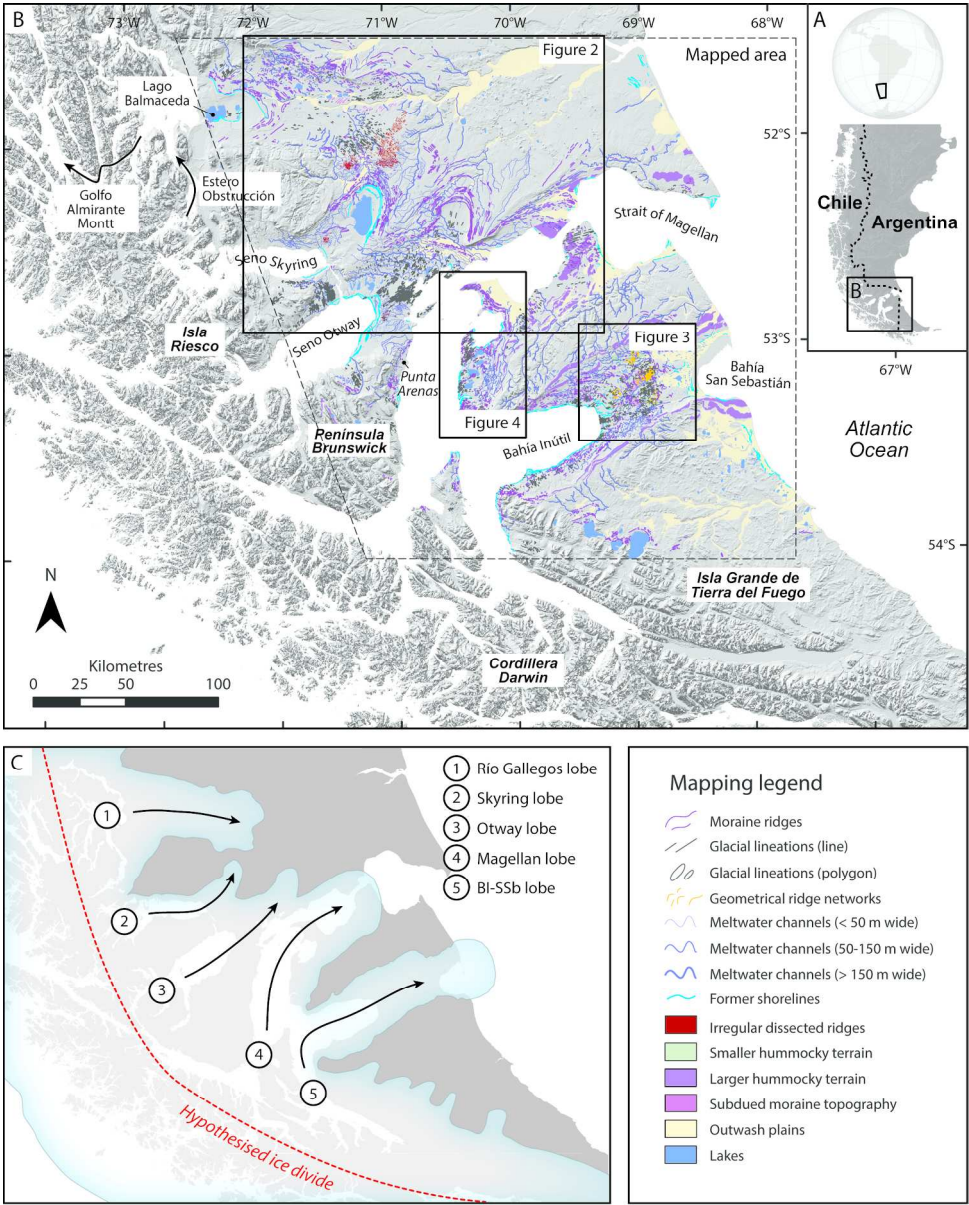

Figure 1. (A) Location of the study area in southern South America. (B) Overview of the geomorphological map from Darvill et al. (2014) showing the locations of figures and locations mentioned in the text. (C) Stylised representation of the southernmost part of the former Patagonian Ice Sheet, highlighting the five former ice lobes discussed in this paper. The approximate position of the ice divide is based on Hulton et al. (2002), but is shown for illustrative purposes only.

183x228mm (300 x 300 DPI)

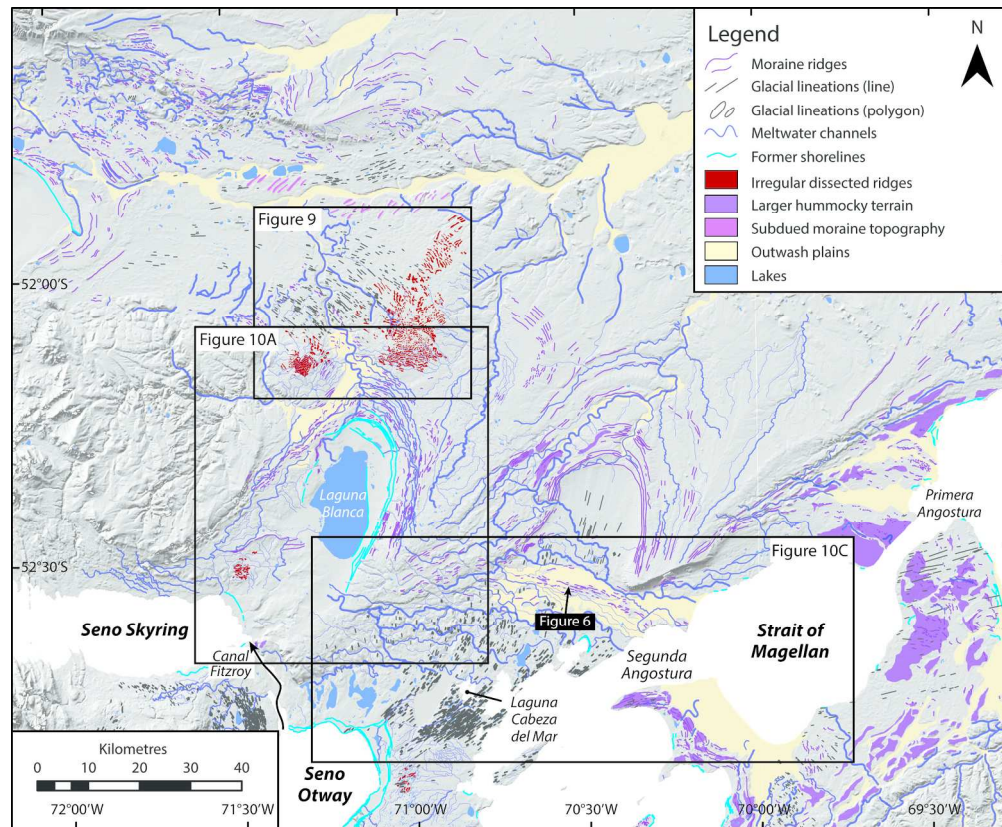

Figure 2. An overview of the glacial geomorphology relating to the Río Gallegos, Skyring, Otway and Magellan lobes, including key locations mentioned in the text (location shown in Figure 1).
184x151mm (300 x 300 DPI)

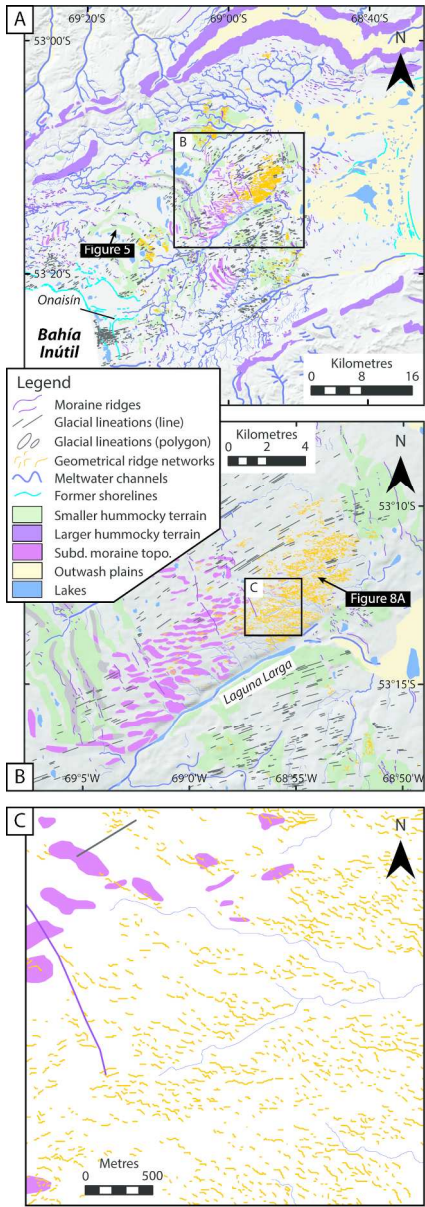

Figure 3. (A) Overview of the glacial geomorphology associated with the centre of the BI-SSb lobe (location shown in Figure 1). Note the spillway marked by former shorelines associated with a proglacial lake that drained at Onaisin through Laguna Larga. (B) Enlargement of the central part of (A) showing cross-cutting relationships between subdued moraine topography and moraine ridges, glacial lineations and smaller hummocky terrain. (C) Enlargement of (B) showing the ordered nature of the regular hummocky terrain mini-ridges and the cross-cutting relationships more clearly.

85x245mm (300 x 300 DPI)

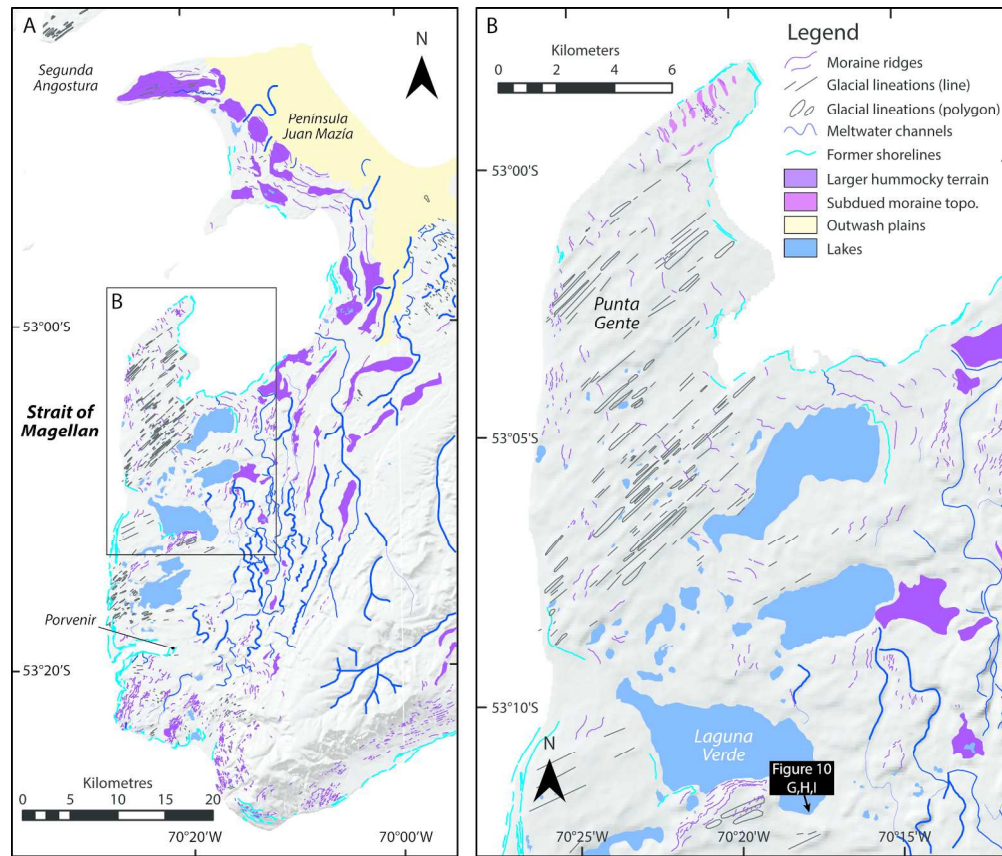

Figure 4. (A) Overview of the glacial geomorphology associated with the Magellan lobe (location shown in Figure 1). Península Juan Mazía may have been the terminus of a surge-like advance (see text). (B) Enlargement of Punta Gente and the large field of elongate drumlins, in places draped by small moraine ridges.

183x156mm (300 x 300 DPI)

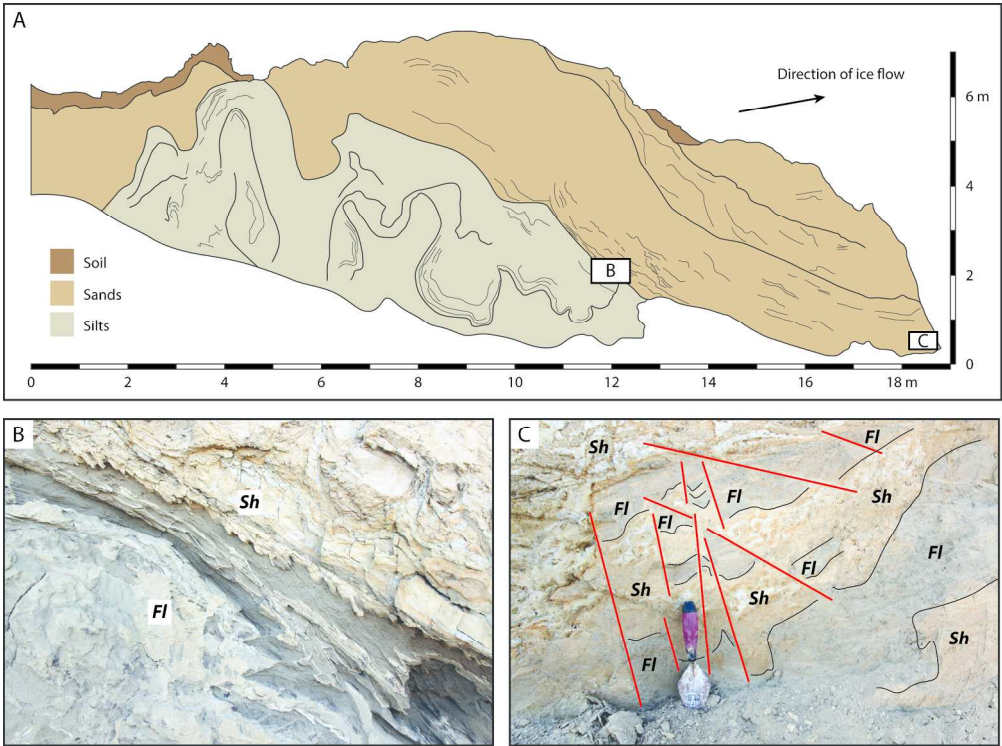

Figure 5. Sketch log (A) and accompanying photographs (B and C) of proglacially tectonised lacustrine silts and sands within an end moraine of the BI-SSb lobe (location shown in Figure 3A). There is a high degree of folding and faulting. The large section suggests that the ice lobe retreated sufficiently for a sizeable proglacial lake to develop, prior to re-advance.
183x136mm (300 x 300 DPI)

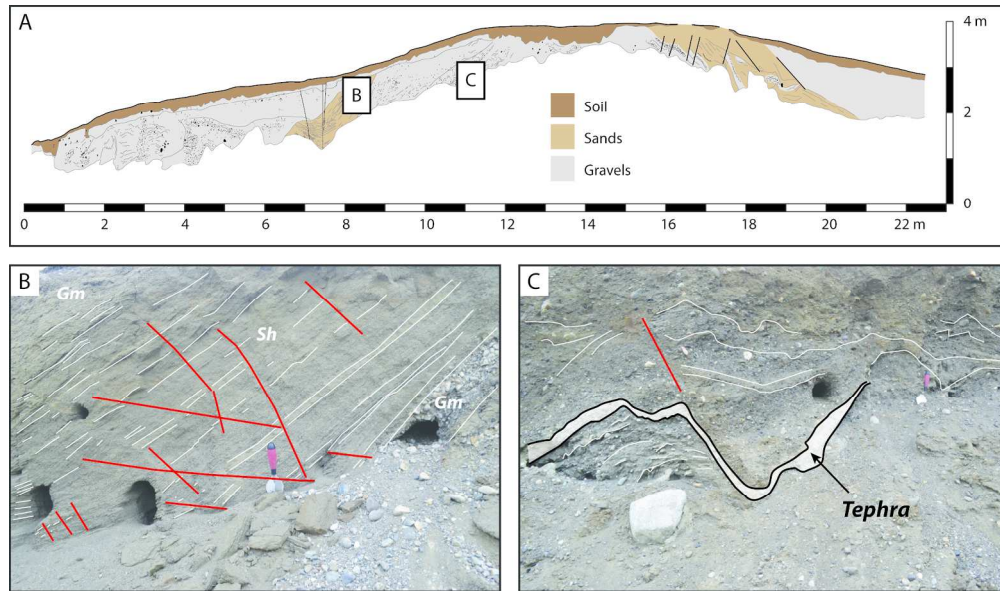

Figure 6. Sketch log (A) and accompanying photographs (B and C) of a glaciotectionised moraine associated with re-advance of the Otway lobe (location shown in Figure 2). The normal thrust faults are particularly highlighted by a deformed tephra layer in (C). The sediments are characteristic of outwash material that was likely deposited during retreat of the ice prior to re-advance and proglacial thrusting.
183x108mm (300 x 300 DPI)

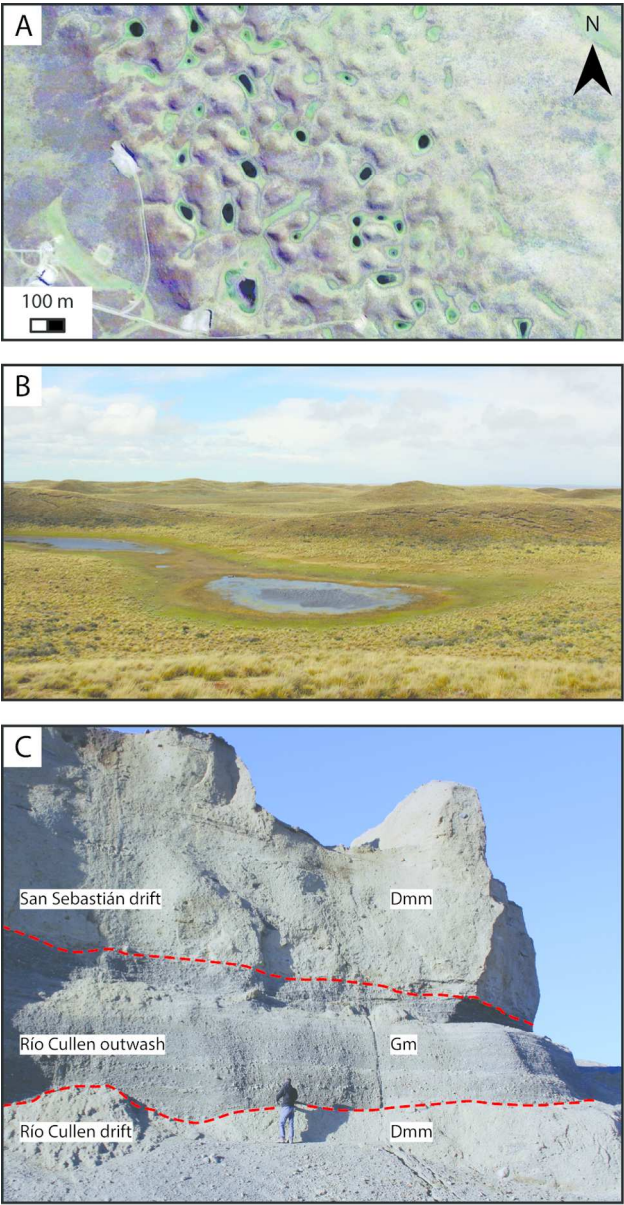

Figure 7. (A) A Google Earth image of larger irregular hummocky terrain from the south side of the BI-SSb lobe. (B) Field photograph of the hummocky topography on the north side of the BI-SSb lobe, illustrating the rounded hills and lakes. (C) A section through the inner band of larger hummocky terrain on the north side of the BI-SSb lobe. The top unit relates to this inner glacial limit (the San Sebastián drift), but overlies an earlier diamict unit and associated outwash (the Río Cullen drift), indicating that the ice lobe re-advanced (person for scale).
85x164mm (300 x 300 DPI)

Figure 8. (A) A Google Earth image of regular hummocky terrain from the centre of the BI-SSb lobe (location shown in Figure 3B). This terrain resembles geometrical ridge networks and could be preserved crevasse-squeeze ridges. To illustrate this, (B) shows a Microsoft Bing Maps image of crevasse-squeeze ridges in front of the surging Brúarjökull glacier in Iceland. Note that although the glaciers in question are markedly different in size, the images are at the same scale.

85x92mm (300 x 300 DPI)

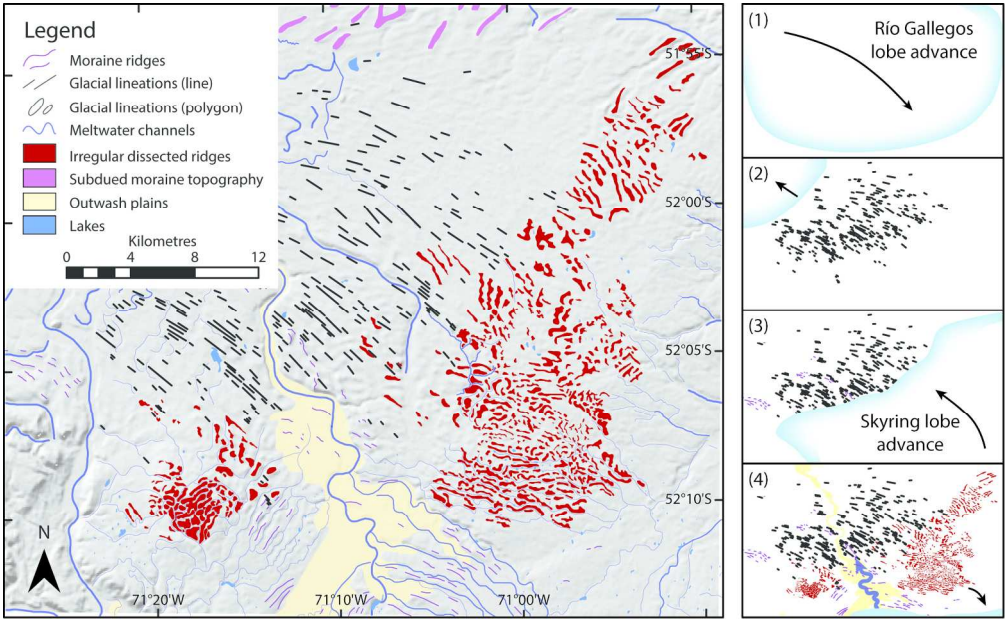

Figure 9. Glacial geomorphology found at the intersection between the Río Gallegos and Skyring lobes (location shown in Figure 2). (1) to (4) show a stylised formation mechanism for the irregular dissected ridge features. (1) The Río Gallegos advances first, creating a swath of drumlins (2), and possibly moraines, that are later overridden by an advance of the Skyring lobe (3). The order is dictated by the flow of meltwater from the Skyring lobe into the Río Gallegos basin (4).

183x112mm (300 x 300 DPI)

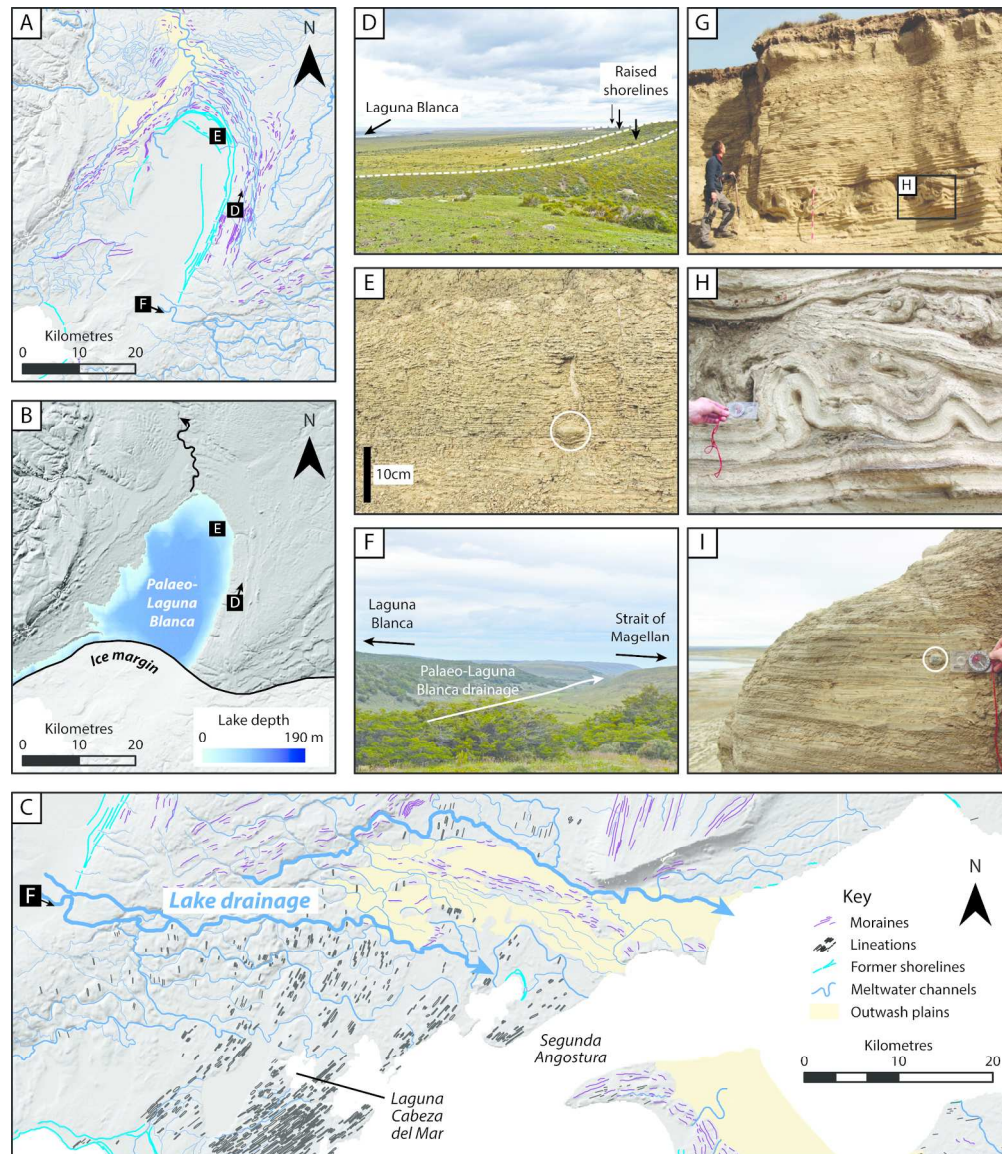

Figure 10. Evidence for proglacial lakes within the study area. (A) shows the geomorphology and (B) the reconstructed ice limit and palaeo-Laguna Blanca proglacial lake just prior to drainage, when discharge flowed northwards. (C) The geomorphological evidence for lake drainage eastward into the Strait of Magellan once the Skyring lobe retreated beyond the bluff separating it from the Otway lobe (locations shown in Figure 2). (D) Raised shorelines, (E) laminated lake sediments with a dropstone circled, and (F) a drainage channel associated with palaeo-Laguna Blanca (locations shown in A and B). (G) Rhythmically laminated sediments from Laguna Verde (see Figure 4 for location). (H) Enlarged part of (G) showing several heavily deformed layers, possibly due to earthquake-induced tectonisation. (I) Dropstones are found within the Laguna Verde sequence (circled).

List of data tables

Table S1. Compilation of ¹⁰Be and ²⁶Al cosmogenic nuclide exposure ages from the study area. Ages have been recalculated. 5

Table S2. Compilation of ³⁶Cl cosmogenic nuclide exposure ages from the study area. Ages have not been recalculated. 6

Table S3. Ages from two depth profiles through outwash associated with glacial limits in the study area. Ages are taken directly from Darvill et al. (2015b) 6

Table S4. Compilation of radiocarbon dates relating to glacier activity within the study area. Ages have been recalculated. 7

1 Age recalculation

In order to apply a broad chronological framework to the geomorphological reconstruction in this study, a large number of cosmogenic nuclide exposure ages and radiocarbon ages were compiled (Tables S1, S2, S3 and S4). The ^{10}Be , ^{26}Al and radiocarbon dates were also recalculated. There is an argument that recalculation may not be necessary because:

1. Uncertainty associated with cosmogenic nuclide exposure ages appears to be dominated by post-depositional effects (Kaplan et al., 2007; Evenson et al., 2009; Darvill et al., 2015a, 2015b) rather than uncertainties associated with age calculation.
2. Many of the landforms that have been exposure dated are older than the landforms used for regional or global ^{10}Be production rate calibrations (these are generally <20 ka; Borchers et al., 2016).

We recalculated ages because many of the original studies were published prior to updated calibration studies (both for cosmogenic nuclide exposure dating and radiocarbon dating). Moreover, whilst many of the ages may be older than the production rate datasets, this is still likely to be a better approximation of age than if older calibration datasets were used, and also creates consistency within our compilation, such that ages are compared on a similar scale. Overall, younger ages within the compilation (e.g. since the global Last Glacial Maximum) are changed little by this recalculation.

1.1 ^{10}Be and ^{26}Al exposure ages

A total of 75 ^{10}Be exposure ages and 13 ^{26}Al exposure ages were compiled for this study, shown in Table S1 (McCulloch et al., 2005b; Kaplan et al., 2007, 2008; Evenson et al., 2009; Darvill et al., 2015b; Sagredo et al., 2011). All exposure ages were recalculated using the CRONUS-earth online calculator version 2.2 (Wrapper script: 2.2; Main calculator: 2.1; Objective function: 2; Constants: 2.2.1; Muons: 1.1 (available at <http://hess.ess.washington.edu/math/>; see Balco et al., 2008). All calibration information was

taken from the original studies, and a density of 2.7 g cm^{-3} was assumed where no density information was provided (reasonable given that all other published sample densities from the study area were either 2.65 g cm^{-3} or 2.7 g cm^{-3}). No erosion correction was applied so that the studies could be directly compared in a simple way, although in reality this is almost certainly unrealistic (Kaplan et al., 2007). The Macaulay River production rate from New Zealand was used (Putnam et al., 2010) because it overlaps at 1σ with a production rate from Lago Argentino in Patagonia (Kaplan et al., 2011) and has been used in other recent dating studies in Patagonia (Boex et al., 2013; Darvill et al., 2015b). The choice between these two production rates does not affect our discussion - the important point is that both production rates are lower than the global rate used in most of the original studies. Likewise, we consistently applied the 'Lm' time-dependent scaling scheme of Lal (1991) and Stone (2000), although the choice of scaling scheme makes little difference within the context of our discussion.

1.2 ^{36}Cl exposure ages

The details of nine ^{36}Cl exposure ages are compiled in Table S2 (Kaplan et al., 2007; Evenson et al., 2009). The dates were not recalculated given that progress in determining local ^{36}Cl production rates has not been made on the same scale as ^{10}Be production (and, by ratio scaling, ^{26}Al production). All ages were considered underestimates in the original studies due to postdepositional erosion and/or exhumation.

1.3 Depth profile exposure ages

Two exposure ages from depth profiles through outwash sediments related to glacial limits are compiled in Table S3, with all data from Darvill et al. (2015). These dates are modelled from numerous depth samples, and the reader is referred to the original study for full details of the modelling process and contextual discussion.

1.4 Radiocarbon ages

Data associated with 114 radiocarbon ages from the study area are compiled in Table S4 (Heusser et al., 1990; Clapperton et al., 1995; Anderson & Archer, 1999; Hall et al., 2013; McCulloch et al., 2005b, 2005a; McCulloch & Bentley, 1998; Uribe, 1982; Heusser, 1987; Porter, 1990; Stern, 1992; McCulloch & Davies, 2001; Kilian et al., 2013; Sagredo et al., 2011). Where the raw ^{14}C ages and errors were available, dates were re-calibrated with CALIB 7.0 (Stuiver et al., 2005) using the INTCAL13 curve (Reimer, 2013). All dates were sorted according to their context as either minimum (MIN) or maximum (MAX) ages for glacier advances, or bracketed (M/M) where they dated material underlain and overlain by glacial sediments.

2 Additional chronological discussion

The relationship between our reconstructed time steps and published chronological constraints is described in Section 6.2 of the main text. However, there are subtleties associated with much of this chronological information that benefit from a more detailed version of this discussion. In this section, we describe the dates available for each ice lobe during each of our reconstructed time steps, and provide the landform context from our reconstruction. It is worth noting that while the dates are from the published literature, we (re-)assign those dates to our eight time steps in this study.

2.1 Time step 1: Pre-global Last Glacial Maximum (gLGM) advance

The Río Gallegos lobe flowed rapidly to its greatest extent during time step 1, creating flowsets FS 1 and FS 2 (Figure 13A in the main text). The extent of the other ice lobes is unclear, but the Skyring lobe cannot have been fully extended because the geomorphology of the Río Gallegos and Skyring lobes overlaps and Skyring drainage later flowed into the former Río Gallegos depression. Cosmogenic ^{10}Be exposure ages of 56.0 ka and 138 ka from the outer limits of the Río Gallegos lobe are substantially younger than the Bella Vista flow, which has been $^{40}\text{Ar}/^{39}\text{Ar}$ dated to 1.17 Ma (Kaplan et al., 2007; Singer et al., 2004; Meglioli, 1992). The Bella Vista flow underlies till deposits thought to relate to the maximum glacial advance and the large difference in these ages may be due to post-depositional processes affecting moraine boulders sampled for exposure dating (Kaplan et al., 2007). We caution that linking distal drift sediments to limits defined by glacial geomorphology is challenging (e.g. Meglioli (1992) also dated flows to 8.0 and 8.5 Ma within this ice lobe); the Bella Vista flow only provides a maximum age for the limit; and it is not inconceivable that the ice lobe extended towards this maximum extent on several occasions.

2.2 Time step 2: Pre-gLGM advance

The Skyring, Otway, Magellan and BI-SSb ice lobes advanced to their maximum extents, whereas the Río Gallegos lobe retreated (Figure 13B in the main text). The Skyring lobe

advanced into the Río Gallegos depression, overriding former moraines and glacial lineations to leave irregular dissected ridges (Section 4.2.3 in the main text). The precise extent and timing of the advances is unclear, and correlation cannot be made between the ice lobes. The ^{10}Be ages of 56.0 ka and 138 ka (Kaplan et al., 2007) in time step 1 could reasonably relate to time step 2 if they were actually deposited by the Skyring lobe. Two additional ^{10}Be ages of 59.4 ka and 173 ka from the Magellan lobe are similarly young compared to local $^{40}\text{Ar}/^{39}\text{Ar}$ ages (Meglioli, 1992; Singer et al., 2004; Kaplan et al., 2007). However, tying dated tills to glacial limits may not be straightforward. It is conceivable that the ice lobes advanced more than once to similar limits at radically different times, possibly due to topographic constraints (Kirkbride & Winkler, 2012; Barr & Lovell, 2014) or erosional feedbacks (Kaplan et al., 2009; Anderson et al., 2012). For example, The BI-SSb lobe was also close to this limit in at least time steps 3 and 4. The four cosmogenic dates available for time steps 1 and 2 may indicate two separate advances at around 173-138 ka and 59-56 ka, but the dates are not apparently in stratigraphic order. These dates also disagree with the conceptual age model for the region (Meglioli, 1992) and do not take into account erosion and/or exhumation processes (Kaplan et al., 2007).

2.3 Time step 3: Pre-gLGM advance

The Río Gallegos lobe continued to recede during time step 3 and the Skyring and Otway lobes retreated to close to the limits of their topographic basins (Figure 13C in the main text). The Magellan lobe may have re-advanced to form FS 11, although this flowset could equally have formed in time step 1 or 2. In the Río Gallegos lobe, two ^{10}Be ages of 56.3 ka and 56.6 ka and three ^{36}Cl ages of 38.1 ka to 55.2 ka are younger than expected (repeat samples; Evenson et al., 2009). However, four ^{10}Be ages of between 37.1 ka and 64.4 ka from interior lateral moraines may have been deposited at a similar time (Sagredo et al., 2011). There are no chronological constraints for the Skyring, Otway or Magellan lobes and correlation between the lobes cannot be made. The BI-SSb ice limit has been ^{10}Be dated (Kaplan et al., 2007, 2008), with twelve ages ranging from 15.2 ka to 57.3 ka, eight of which are within 26.8

ka and 33.0 ka. In addition, two ^{26}Al dates of 24.8 ka and 30.4 ka and four ^{36}Cl dates of 18.7 ka, 25.2 ka, 27.1 ka and 51.5 ka have been reported (Kaplan et al., 2007; Evenson et al., 2009). Post-depositional erosion and exhumation may have affected many of these boulder ages (Kaplan et al., 2007), so Darvill et al. (2015b) used a $^{10}\text{Be}/^{26}\text{Al}$ depth profile through outwash sediments to obtain an independent estimate of age for the BI-SSb lobe. This demonstrated that the limit was deposited during the last glacial cycle, possibly around 45.6 ka.

Numerous dating campaigns have yielded ages younger than previously thought, and a best estimate of age for time step 3 may be somewhere between 26.8 ka and 57.3 ka. The large spread of ages could result from post-depositional processes, possibly linked to gradual melt-out of the dead ice in hummocky terrain or boulder erosion (Kaplan et al., 2007; Schomacker, 2008; Darvill et al., 2015a). The latter could explain the offset between the dominant cluster of boulder ages between 27.0 ka and 36.2 ka, and the depth profile at 45.6 ka, in which case the depth profile would be a better estimate of the time of deposition.

2.4 Time step 4: Pre-gLGM advance

In time step 4, the Skyring and Otway lobes retreated to skirt the edges of their respective basins, with the Otway lobe possibly re-advancing to form FS 7 (Figure 13D in the main text). The Magellan lobe retreated to Primera Angostura and the Río Gallegos lobe continued to retreat, possibly re-advancing slightly to deposit FS 3. The BI-SSb lobe re-advanced close to the limit of time step 3, yielding two ^{10}Be dates of 24.3 ka and 224.1 ka (Kaplan et al., 2007). These dates are ambiguous, but a depth-profile through associated outwash yielded a more robust age of ca. 30.1 ka (Darvill et al., 2015b). Like time step 3, there is scatter in the boulder ages, perhaps due to post-depositional processes. For the Magellan lobe, four ^{10}Be ages between 24.8 ka and 36.9 ka and two ^{26}Al ages of 31.0 ka and 32.6 ka (Kaplan et al., 2007) imply that the limit may have been deposited at a similar time to that of the BI-SSb lobe. In addition, we suggest that four ^{10}Be dates of 27.4 ka to 29.9 ka on Península Juan Mazía, previously ascribed to a later advance (McCulloch et al., 2005b;

Kaplan et al., 2008), may have been deposited at this time given the similarity in ages. There are no ages for the Río Gallegos, Skyring or Otway lobes and it remains unclear to what extent these lobes acted in a similar manner.

2.5 Time step 5: Re-advances, rapid flow and lake drainage

The Río Gallegos, Magellan and Skyring lobes retreated during time step 5, with the latter triggering the development of a proglacial lake – palaeo-Laguna Blanca – which may have further facilitated ice loss from a calving front (Figure 13E in the main text). This lake drained northwards into the Río Gallegos depression, indicating recession of the Río Gallegos lobe. The Otway lobe re-advanced significantly, forming FS 8 around Laguna Cabeza del Mar and shifting the ice divide between the Otway and Magellan lobes south-eastward into the present-day Strait of Magellan. The BI-SSb lobe also re-advanced to a limit close to Bahía San Sebastián, depositing a large terminal moraine that is still preserved east of Laguna Larga and forming FS 17. The re-advances of these two ice lobes may have been in response to rapid ice flow, or possible surge-like activity. Thus, between time steps 4 and 5, all ice lobes receded and the Otway and BI-SSb lobes re-advanced. There are no chronological constraints for any of the ice lobes in this time step, but the moraines deposited by the Otway can be correlated with those of the Skyring and Magellan lobes.

2.6 Time step 6: Re-advances, rapid flow and lake drainage

All ice lobes retreated during this time step (Figure 13F in the main text). The Skyring, Otway and Magellan lobes did not retreat far because the potentially catastrophic drainage of palaeo-Laguna Blanca passed from in front of the Skyring lobe east to south-easterly in front of the Otway and Magellan lobes. It is unclear how far the Río Gallegos and BI-SSb lobes retreated during this time step, but the presence of deformed lacustrine sediments in re-advance moraines of the BI-SSb lobe in time step 7 suggests that this ice lobe must have retreated sufficiently for a pro-glacial lake to develop. Again, there are no chronological constraints for any of the ice lobes in this time step, but we note that for the Skyring, Otway

and Magellan lobes, time steps 5 and 6 are broadly constrained by dates in the Magellan lobe for time steps 4 and 7, and that the limits can be correlated reasonably robustly across the three ice lobes. Dating the drainage of palaeo-Laguna Blanca would improve this chronology and test our interpretation of the dates for time steps 4 and 7.

2.7 Time step 7: The gLGM

This time step has previously been defined as the gLGM limit (Figure 13G in the main text). There are no supporting ages for the Río Gallegos, Skyring and Otway lobes, although they were likely situated within the present-day fjords, with the termini of the Skyring and Otway lobes splitting after time step 6. The Magellan and BI-SSb lobes had retreated – although it is not clear how far – and re-advanced during this time step, possibly displaying surge-like behaviour and forming FS 13 and FS 18. The Magellan lobe has been ^{10}Be dated four times on Península Juan Mazía to between 18.3 ka and 23.2 ka. The BI-SSb lobe has also been dated with 18 ^{10}Be dates yielding ages of between 15.6 ka and 55.8 ka, one ^{26}Al date of 26.6 ka, and two ^{36}Cl dates of 22.3 ka and 54.8 ka (McCulloch et al., 2005b; Kaplan et al., 2007, 2008; Evenson et al., 2009). Sixteen of the ^{10}Be dates fall between 17.6 ka and 24.9 ka. The reason for the scatter in ages is unclear, although the ^{10}Be date of 55.8 ka may be due to inheritance, given most of the dates are from a large erratic boulder train on the south-eastern side of Bahía Inútil (Darvill et al., 2015a). Nonetheless, the dates for the Magellan and BI-SSb lobes generally support the assertion that this time step relates to the gLGM.

2.8 Time step 8: Rapid retreat

All of the ice lobes were in full post-gLGM retreat during this time-step, likely developing proglacial lakes in front of their receding margins that could have increased the rate of ice retreat due to frontal calving (Figure 13H in the main text; Porter et al., 1992; Kilian et al., 2007). The Skyring and Otway lobes were located well within their respective fjords, with cores suggesting ice-free conditions in Seno Skyring and Seno Otway dated to at least 14.8 ka and 14.7 ka, respectively, using radiocarbon dating and tephrostratigraphy (Kilian et al.,

2013). Kilian et al. (2007) suggested that this was part of a rapid retreat of the Skyring lobe, likely linked in part to proglacial calving. The Magellan lobe has been ^{10}Be dated to 20.4 ka and 20.6 ka on Península Juan Mazía and also 15.1 ka and 16.8 ka on the western lateral side of the lobe (Kaplan et al., 2008), perhaps indicating relatively rapid retreat of the ice lobe during and after this time step, and supporting ice recession by ca. 22 ka, as indicated by luminescence ages on the western side of the Strait of Magellan (Blomdin et al., 2012). The BI-SSb lobe has yielded five similar ^{10}Be dates between 18.7 ka and 21.3 ka (McCulloch et al., 2005b; Kaplan et al., 2008), as well as four ^{10}Be dates from below the proglacial lake shoreline suggesting that drainage may have occurred between 14.4 ka and 8.3 ka (Evenson et al., 2009). Numerous radiocarbon dates suggest that retreat of the Magellan and BI-SSb ice lobes was well under way by at least 14–15 ka (Clapperton et al., 1995; McCulloch & Bentley, 1998; McCulloch et al., 2005b), although the presence of the Reclús tephra within lake sediments suggests full retreat and lake drainage cannot have been before ca. 14.3 ka (McCulloch et al., 2005a). The rapid retreat, and possible collapse, of the BI-SSb lobe during and after this time step is supported by radiocarbon dates in the accumulation area of the lobe in central Cordillera Darwin that suggest that the constituent outlet glaciers that formed the ice lobe in this time step may have retreated into small interior fjords as early as 16.8 ka (Hall et al., 2013).
